Abstract

The problem of a pressure or volume increase due to the vertical redistribution of two substances with differing compressibilities is considered and compared with a previous treatment. Modified expressions for the pressure and volume changes are obtained using the general equation of state with constant compressibility. The effects of gas and melt compressibilities, and also of the solubility of gas in floating bubbles, on pressure and volume changes in magmatic systems are discussed. Very different conclusions from those in the previous treatment are found.

1. Introduction

This study was motivated by a recent paper (Sahagian and Proussevitch, 1993) dealing with 'an advective overpressure' in volcanic systems. The idea that these authors applied to explain the physics of gas overpressure in magma chambers consisted of a pressure increase due to the transport of a more compressible material (gas) from depth to the surface of a vessel of fixed volume. This approach is not new, and in a follow-up comment (Sahagian, 1993) one of the authors referred to the literature already existing on this subject (e.g., Steinberg et al., 1989), though his list of references is not complete. Here, I briefly review the physical phenomenon that was discussed in these earlier publications, which were aimed at understanding the physics of volcanic gas explosions. To the author's knowledge the first publications on this subject were by Czekaluk (1961, 1968), who analyzed the thermodynamics of gas solubility in a vertical liquid column in a gravity field (retrograde solubility). He described the same type of experiment as in Sahagian and Proussevitch (1993), but used mercury and an air bubble in a closed steel cylindrical vessel equipped with a manometer. As a result of the air bubble rising from the bottom to the top, the pressure in the vessel increased by $\rho g H$ where ρ is the liquid density, g is the acceleration due to gravity and H is the height of the vessel. Czekaluk argued that this mechanism of pressure increase can explain the development of overpressure in oil and gas deposits. Later, in a publication by Knothe and Litwiniszyn (1975), this experiment was repeated with the use of a cylindrical glass vessel, the bottom of which was connected to a U-tube. The liquid and the bubble were represented by water and a rubber balloon filled with air, respectively. The pressure increase was measured by the change of water level in the U-tube. Steinberg et al. (1984, 1989) elaborated this simple physical demonstration into a series of experiments dealing with the simulation of volcanic pressure growth. Their experiments aimed to understand the time dependence of pressure increase where not only a single bubble but rather a jet of bubbles ascended from the
